

Chapter 5d: PSoC 6 Low Power

After completing this chapter, you will understand various low power concepts and how to use the Low Power Assistant (LPA).

5d.1 Overview

If we think in the context of Low Power, not only do we want to be able to configure and control how every part of the system works, such as the MCU or Wi-Fi, but we also want configurability and control over how the parts of the system interact with each other. We also want seamless integration with the RTOS, peripherals, and connectivity subsystems.

Plus, it must work just fine in a real-world environment flooded with packets sent to and from hundreds of hotspots and Bluetooth devices around us, as well as other electromagnetic impulses we don't care about. "Works just fine" in the context of Low Power means the battery lasts as long as it is expected by the customer of your "Thing". Save more energy and you win.

ModusToolbox provides tools and middleware to set up and use the low power features of the PSoC 6 MCU and the connectivity devices on your board. We are referring to this set of tools and middleware as the Low Power Assistant. It consists of:

- **Device Configurator:** Used to configure the peripherals and system resources of the PSoC 6 MCU, configure the low power features of the connectivity device, such as wakeup pins, packet filters, offloads for Wi-Fi, as well as Bluetooth low power. The Device Configurator can also be

used to configure the RTOS integration parameters such as the System Idle Power Mode for Mbed OS. See the Mbed OS Low Power chapter for more details.

- Low Power Assistant (LPA) middleware: This consumes the configuration generated by the Device Configurator, then configures and handles the packet filters, offloads, host wake functionality, etc.

The Low Power Assistant feature is supported for all PSoC 6 MCUs as well as for the CYW43012 and 4343W connectivity modules. The combination of PSoC 6 and CYW43012 offers the lowest power consumption and is available on the CY8CKIT-062S2-43012.

5d.2 Low Power Documentation and Collateral

The best starting point to learn about the Low Power Assistant feature and low power in general is the dedicated Application Note listed below. It includes the references to the code examples which use the LPA library. The LPA library offers online documentation with quick start guides that show you how to setup and test every feature.

Our exercises are mostly based upon the quick start guides offered in the [LPA Middleware API Reference Guide](#).

5d.2.1 Application Note

An excellent source of information that you could start from if you didn't go through this chapter is the low power system design application note. Reading it after this chapter will help you to refresh and reinforce the knowledge you have just gained.

- [AN227910 - Low-Power System Design with CYW43012 and PSoC 6 MCU](#)

5d.2.2 Low Power Assistant Documentation

The LPA library and its top-level README.md file can be found at:

- <https://github.com/cypresssemiconductorco/lpa>

As with most libraries, there is an API guide included in the library:

- https://cypresssemiconductorco.github.io/lpa/lpa_api_reference_manual/html/index.html

5d.3 Guide to this chapter

The Low Power Assistant feature can be used in various flows and we are extending its capabilities. For this chapter, we will be performing exercises using the [CY8CKIT-062S2-43012](#) kit. The kit guide explains how to measure power consumption and where to connect the probes.

The general development flow in the context of Low Power remains the same as for any other design:

- Get Code Examples from <https://github.com/cypresssemiconductorco> or start from an empty project and add the Low Power Assistant middleware to your project.
- Configure the PSoC 6 MCU and connectivity device for low power using the Device Configurator.
- Flash the project and measure the power consumption.

This chapter does not cover the Power Estimator Tool. You can go through the <https://github.com/cypresssemiconductorco/cype> example to use the Power Estimator tool available in your ModusToolbox Installation.

5d.4 Hardware Setup and Power Consumption Measurements

For the purposes of this chapter, we will be using the [CY8CKIT-062S2-43012](#) kit. We will be performing the measurements using a multimeter. If available, it is recommended to use a power analyzer such as a KeySight [N6705B](#). The use of a KeySight N6705B is explained in the low power system design application note referenced earlier.

In order to measure the power consumption on the [CY8CKIT-062S2-43012](#) board configure the multimeter as an ammeter and connect the probes across one of the jumpers depending on which current you want to measure:

| Power Rail | Description | Multi-Meter Connection |
|------------|---------------------|------------------------|
| PSoC 6 Vdd | PSoC 6 Main Power | J15 |
| VBAT | CYW43012 Main Power | J8 |

You can use USB connection to the KitProg to supply power to the kit, but ensure you disconnect the board from the power supply before connecting and disconnecting the power measurement probes.

Detach the TFT shield from the board as we won't need it for the exercises. Also, remove jumper J25 so that you are not measuring current consumed by the onboard potentiometer.

Note: Turn on the multimeter before powering the kit via the USB connection to the KitProg - the multimeter path is high impedance when it is turned off.

Note: Do not disconnect or turn off the multimeter while the kit is powered.

5d.5 Low Power Assistant for PSoC 6

This section will teach you how to improve the power consumption in projects using the PSoC 6 solution in ModusToolbox. Keep in mind that with ModusToolbox we provide the set of tools that enable you to work in various kinds of environments, IDEs, and RTOS ecosystems. The Low Power Assistant is not an exception but for the exercises we will use the Eclipse IDE.

In this part of the training we will select two ModusToolbox code examples and will try to improve the power consumption while preserving the original functionality as much as possible. We will start with the blinky example, and then will improve the power consumption for a CapSense code example. We will use non-RTOS versions of the code examples. We will use the same [CY8CKIT-062S2-43012](#) board we have used in previous exercises.

5d.5.1 Exercise 1: Making Hello World Energy Efficient

Initial Steps

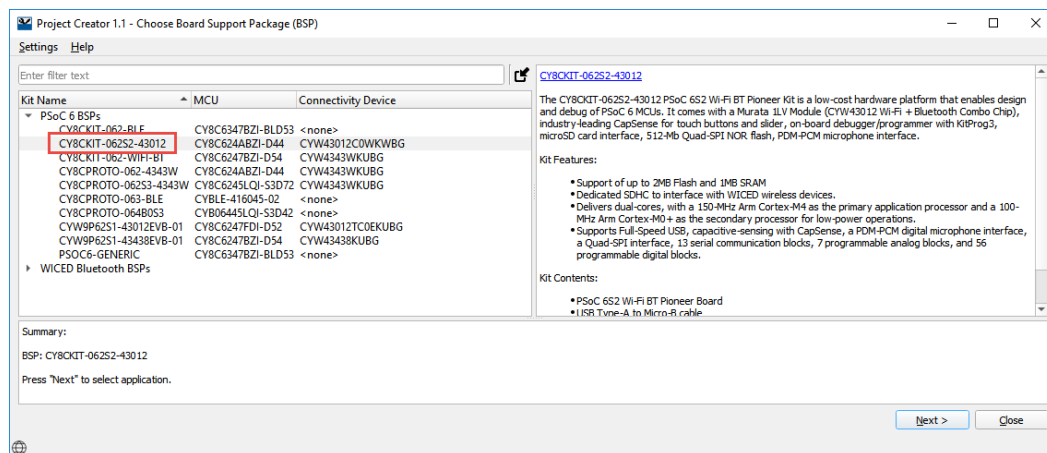

1. Disconnect the board from your computer's USB.
2. Remove the TFT shield and remove jumper J25 to disconnect the potentiometer.
3. Remove the jumper form J15 and connect an ammeter across the pins to measure the PSoC 6 current consumption.
4. Turn the ammeter on. Reconnect the board to your computer's USB.

Note: Use the connection to the ammeter for measuring mA. When making measurements, you may need to switch the setting dial back and forth between μA and mA depending on the current being measured. It is best to start out in the mA setting.

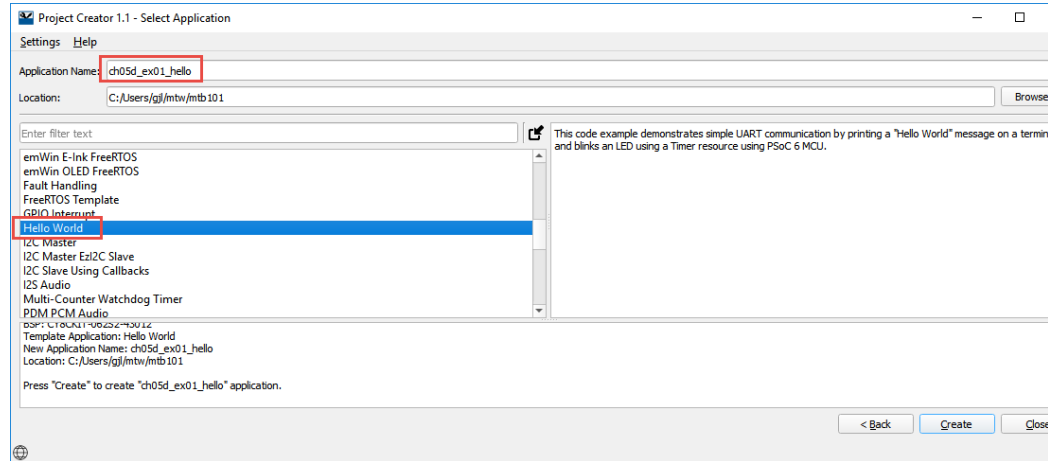

5. Start the Eclipse IDE and create new application for the CY8CKIT-062S2-43012 kit.

6. Select the **Hello World** application.

- a. Change the name to **ch05d_ex01_hello**.
- b. Click **Create** and then **Close** when the application is created.

7. Build the application and program the board.

After programming, the application starts automatically. Verify that the application works as expected: LED blinks.

8. Launch a UART terminal (baud rate = 115200).

- a. Connect to the kit and press Enter.
- b. Observe the LED stops blinking.
- c. Press Enter again and observe the LED resumes blinking.
- d. Stop the blinking while the LED is off (so that we can measure the current without the LED's contribution).

9. Measure current consumption. What is the consumption you see?

_____ (Baseline)

Improve Power Consumption

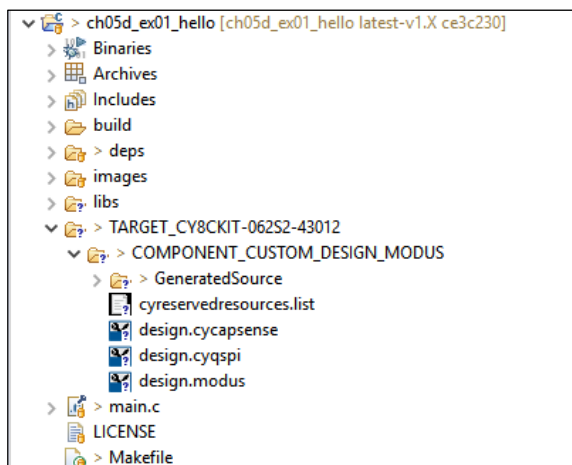

Now we will change regulator settings and reduce clock speeds to improve power consumption. Note that slowing clocks will not always lead to lower power - sometimes, it is better to speed up clocks so that processing can be done quicker allowing the device more time sleeping.

First, we will create a custom design.modus file for our application so that we can make changes without modifying the BSP files directly.

10. Create a new directory in the project's root directory called *TARGET_CY8CKIT-062S2-43012*.

- a. Copy the entire directory from *libs/TARGET_CY8CKIT-062S2-43012/COMPONENT_BSP_DESIGN_MODUS* to the new directory that you created.
- b. *Rename* the new directory *COMPONENT_CUSTOM_DESIGN_MODUS*. The hierarchy should look like this when you finish:

11. Edit the Makefile as follows and save it when you are done:

- a. Add *CUSTOM_DESIGN_MODUS* to the *COMPONENTS* variable.
`COMPONENTS+=CUSTOM_DESIGN_MODUS`
- b. Add *BSP_DESIGN_MODUS* to the *DISABLE_COMPONENTS* variable.
`DISABLE_COMPONENTS+=BSP_DESIGN_MODUS`

12. Now that we have our own design.modus file, open the Device Configurator by double-clicking on the design.modus file in your CUSTOM DESIGN MODUS directory.

This is the safest thing to do because the Quick Panel may still open the version from the BSP until you switch between applications. Verify in the banner that you have opened the correct copy.

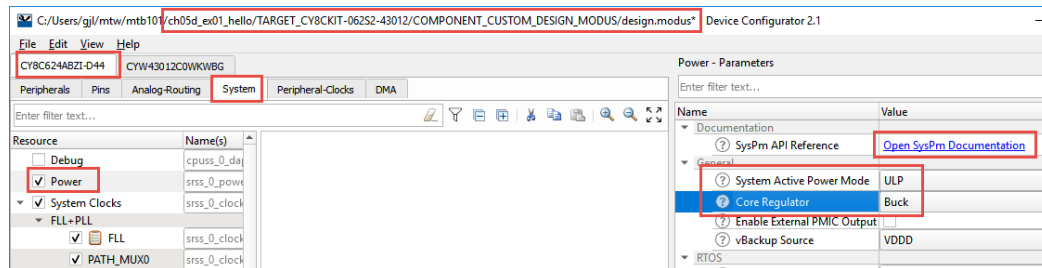

13. Select the **CY8C624ABZI-D44 > System** tab.

14. Select the Resource **Power**.

In the in the **Power – Parameters** pane, change the following parameters:

- **System Active Power Mode:** LP -> ULP
This configures the system for Ultra Low Power. See the SysPM API reference for the clock frequency and current consumption requirements a system must meet to allow the user of ULP mode.
- **Core Regulator:** Normal Current LDO -> Buck
This configures the core to use the Buck regulator instead of the LDO regulator. This regulator consumes less power but will result in more power supply ripple. See the device datasheet for details.

15. Select the Resource **System Clocks > FLL + PLL > FLL**

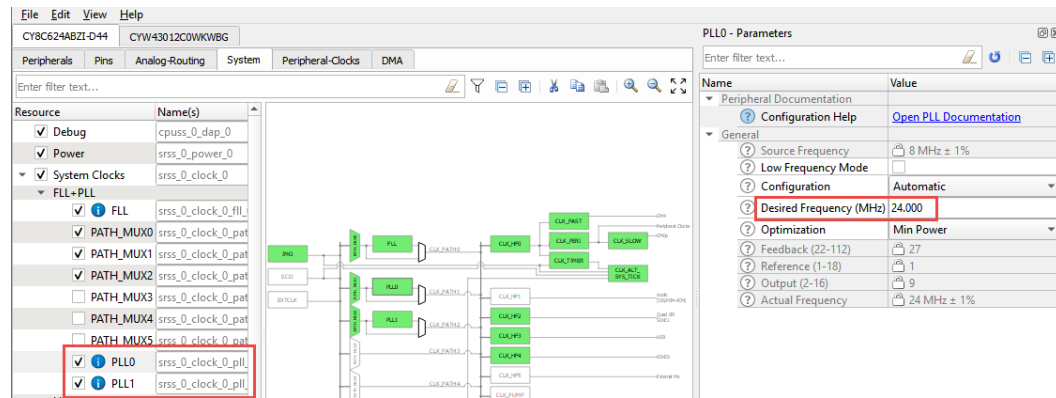

Note: You can select a clock to set its parameters either by clicking on it from the list in the Resource pane or by clicking on it in the clock tree diagram. Likewise, you can enable/disable a clock or path by using the checkbox in the resources pane or by double-clicking on it in the clock tree diagram.

16. In the **FLL – Parameters** pane change the Desired Frequency (MHz) to 24:

17. In the **PLL0 – Parameters** and **PLL1 – Parameters** panes change the Desired Frequency (MHz) to 24:

18. Click **File > Save** and close the configurator.
19. Build and program the application.
20. Verify that the application works as expected.
21. Measure current consumption again with the LED off. What is the consumption you see?

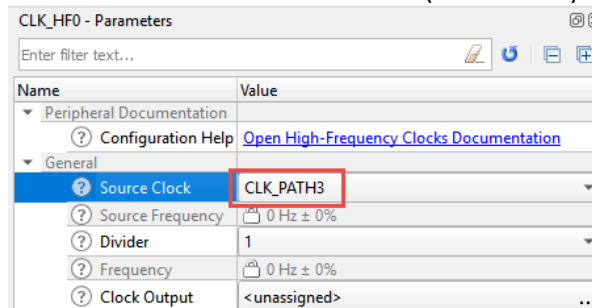

_____ (Lower Power Regulators and Slower Clocks)

Disable Unused Resources

Next, we will disable Unused Resources and further slow the high frequency clock CLK_HF0 by changing its source.

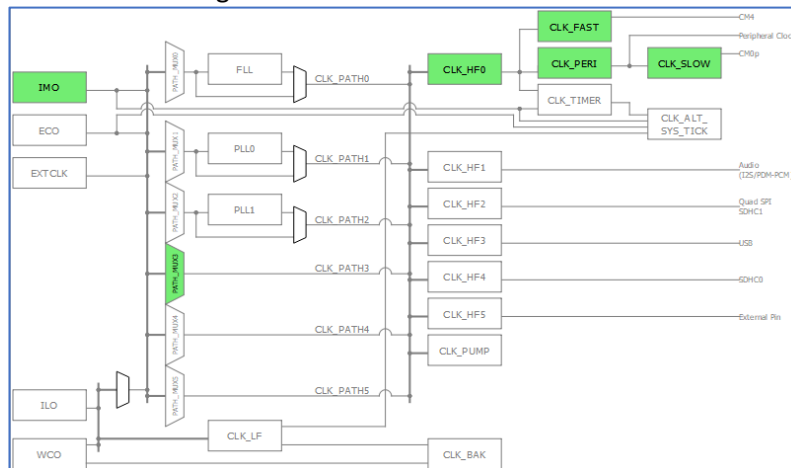

22. Open the Device Configurator by double-clicking on the custom design.modus file.
23. Navigate to **CY8C624ABZI-D44 > System** tab
24. Expand the Resource **System Clocks** and do the following:
 - a. Change the source for CLK_HF0 to CLK_PATH3. This selects the IMO (8 MHz) as the clock source instead of the FLL (min 24MHz).

- b. Uncheck all listed clocks except these:
 - FLL + PLL
 - PATH_MUX3 (Used to mux the IMO to CLK_HF0)
 - High Frequency
 - CLK_FAST (CM4 clock)
 - CLK_HF0 (Source for CLK_FAST)
 - CLK_PERI (Peripheral clock)
 - CLK_SLOW (CM0+ clock)
 - Input
 - IMO (Internal Main Oscillator - main clock source - 8 MHz)
 - Miscellaneous (all unchecked)

The clock tree diagram will look like this:

25. Uncheck (Disable) Resource **Debug**. This disables the ARM debug port.

26. Navigate to the **Peripherals** tab.

27. Uncheck the Resource **CSD (CapSense, etc.) 0** in the **System** section.

28. Navigate to the **Pins** tab.

29. Uncheck all pins.

The pins for HAL peripherals such as the LEDs are reserved in the BSP, so they don't need to be checked in the configurator. You will be disabling pins used for Debug, CapSense, and the WCO.

Note: Click the "+" button to expand all ports.

Note: Click the filter button to show only selected pins.

30. Navigate to the **Peripheral-Clocks** tab.

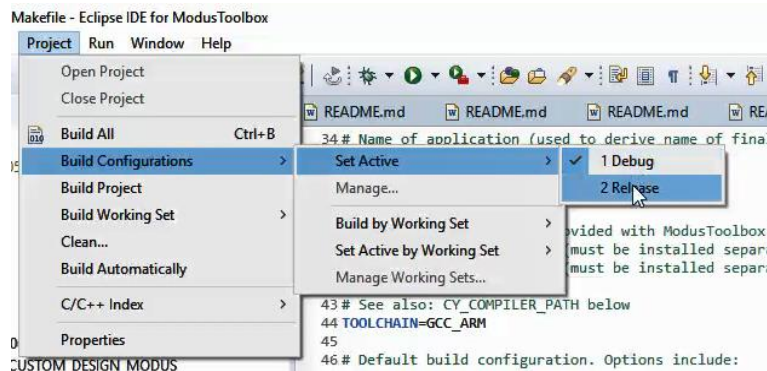

31. Uncheck Resource **8-bit Divider 0**. This was used by CapSense.

32. Click **File > Save**.

33. In the Eclipse IDE menu, select **Project > Build Configurations > Set Active > Release**.

34. Build and program the application.

35. Verify that the application works as expected.

36. Measure current consumption with the LED off. What is the consumption you see?

_____ (Disable Unused Resources)

Enable Sleep

Next, we'll do some code changes to further improve the power. Instead of polling continuously to see if the UART has a new value and to see if the timer has expired, we will put the CPU into sleep mode until the timer expires. When the timer expires, we will:

- Read the UART to see if the user has changed the toggle state
- Toggle the LED (if LED blinking is enabled)
- Go back to sleep

This allows the CPU to be asleep much of the time.

37. Open the main.c file and add the following global variable:

```
bool uart_command_flag = false;
```

38. Replace the infinite loop with the following code:

```
for(;;)
{
    cyhal_syspm_sleep();
    if(cyhal_uart_getc(&cy_retarget_io_uart_obj, &uart_read_value, 1) \
        == CY_RSLT_SUCCESS)
    {
        if (uart_read_value == '\r')
        {
            led_blink_active_flag ^= 1;
            uart_command_flag = true;
        }
    }

    if(timer_interrupt_flag)
    {
        timer_interrupt_flag = false;
        if (uart_command_flag)
        {
            uart_command_flag = false;
            if (led_blink_active_flag)
            {
                printf("LED blinking resumed\r\n");
            }
            else
            {
                printf("LED blinking paused \r\n");
            }
            printf("\x1b[1F");
        }
        if (led_blink_active_flag)
        {
            cyhal_gpio_toggle((cyhal_gpio_t) CYBSP_USER_LED);
        }
    }
}
```

39. Build and program the application. Verify that the application works as expected.

40. Measure current consumption with the LED off. What is the consumption you see?

_____ (Utilize Sleep Mode)

Enable Deep Sleep

Next let's add in deep sleep operation. We will need to change the timer that does the blinking to a low power timer (lptimer) and the low frequency clock (CLK_LF) that it uses so that the device will have a way to wake back up.

We will also remove the UART because it will not operate in deep sleep mode and since we expect to be in deep sleep most of the time, it won't do us any good.

1. Open the Device Configurator by double-clicking on the custom design.modus file.
2. Go to the System tab and under the Resource **System Clocks** do the following:

Enable the ILO
Enable CLK_LF
Set the CLK_LF source to ILO

3. Open the main.c file and change `cyhal_syspm_sleep` to `cycal_syspm_deepsleep`.
4. Change the type for the `led_blink_timer` global variable:

```
cyhal_lptimer_t led_blink_timer
```

5. Replace the `timer_init` function with the following code:

```
#define LPTIMER_MATCH_VALUE (32767)
#define LPTIMER_INTR_PRIORITY (3u)

void timer_init(void)
{
    /* Initialize lptimer. */
    cyhal_lptimer_init(&led_blink_timer );

    /* CLK_LF is 32,768 Hz, so 32,767 counts give us a 1 second interrupt
    */
    cyhal_lptimer_set_match(&led_blink_timer, LPTIMER_MATCH_VALUE);

    /* Register the interrupt callback handler */
    cyhal_lptimer_register_callback(&led_blink_timer, isr_timer, NULL);

    /* Configure and Enable the LPTIMER events */
    cyhal_lptimer_enable_event(&led_blink_timer,
        CYHAL_LPTIMER_COMPARE_MATCH, LPTIMER_INTR_PRIORITY, true);

    /* Reload/Reset the Low-Power timer to get periodic interrupt. */
    cyhal_lptimer_reload(&led_blink_timer);
}
```

6. Replace the `isr_timer` function with the following code:

```
static void isr_timer(void *callback_arg, cyhal_lptimer_event_t event)
{
    (void) callback_arg;
    (void) event;

    /* Set the interrupt flag and process it from the main loop */
    timer_interrupt_flag = true;

    /* Reload/Reset the LPTIMER to get periodic interrupt */
    cyhal_lptimer_reload(&led_blink_timer);
}
```

Note that the second argument's type has changed from `cyhal_timer_event_t` to `cyhal_lptimer_event_t`. Therefore, you will also have to update the function declaration at the top of `main.c`.

7. Remove all code associated with the retarget IO library and UART. Specifically:

Include for `cy_retarget_io.h`
Global Variables `cy_retarget_io_uart_obj`, `uart_read_value` and `uart_command_flag`
Call to `cy_retarget_io_init`
All `printf` statements
If statement and block of code for `if(cyhal_uart_getc...`
If statement and block of code for `if(uart_command_flag)`

You can optionally remove the retarget-io library from the application.

8. Build and program the application.
9. Verify that the application works as expected.
10. Measure current consumption with the LED off. What is the consumption you see?

_____ (Utilize Deep Sleep Mode)

5d.5.2 Exercise 2: Improving Power Consumption for the CapSense Buttons and Slider Example

There are certainly more interesting things to do other than the Blinky, and CapSense is one of them. Let's see how to improve the power consumption for the CapSense code example.

Note that we will reduce the frequency of several clocks in this exercise which will affect the CapSense scan times. In this case, the design has enough margin to still operate properly. In a real application, you may need to re-tune CapSense parameters after changing clocks that affect it.

Create CapSense Design

1. Create the *CapSense Buttons and Slider* Example for the CY8CKIT-062S2-43012 board using the Eclipse IDE. Name the application **ch05d_ex02_capsense**.
2. Build and Program the board. After programming, the application starts automatically.
3. Verify that the application works as expected by touching the slider, the LED brightness should correspond to the touch position. The buttons can be used to turn the LED on/off.
4. Measure current consumption with the LED off (touch button 1 to turn the LED off) and on (touch button 0 and slide the slider to the right for maximum brightness).

What is the consumption you see?

LED off: _____ LED on: _____ (Baseline)

Improve Power Consumption

Now do the following steps to improve power consumption of the application.

5. Start by creating a custom copy of the device configuration from the BSP.
 - a. Create a new directory in the project's root directory called *TARGET_CY8CKIT-062S2-43012*.
 - b. Copy the entire directory from *libs/TARGET_CY8CKIT-062S2-43012/COMPONENT_BSP_DESIGN_MODUS* to the new directory that you created.
 - c. Rename the new directory *COMPONENT_CUSTOM_DESIGN_MODUS*.

6. Edit the Makefile as follows and save when you are done:
 - a. Add *CUSTOM_DESIGN_MODUS* to the *COMPONENTS* variable.
`COMPONENTS+=CUSTOM_DESIGN_MODUS`
 - b. Add *BSP_DESIGN_MODUS* to the *DISABLE_COMPONENTS* variable.
`DISABLE_COMPONENTS+=BSP_DESIGN_MODUS`

7. Open the Device Configurator by double-clicking on the custom design.modus file. Verify in the banner that the correct file is opened.

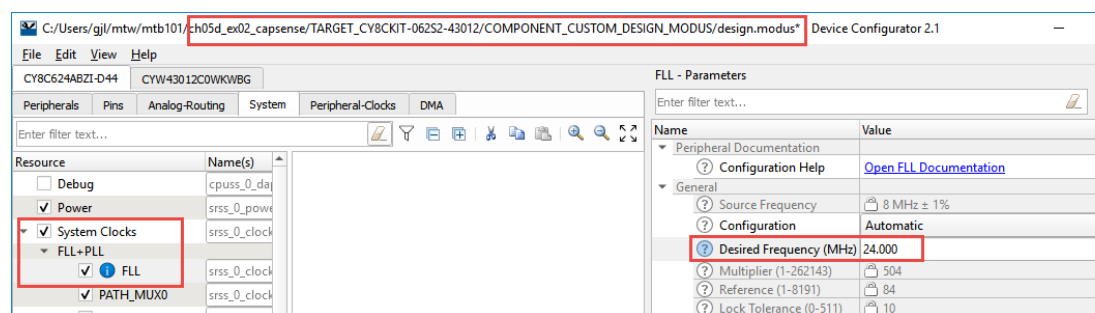

8. Select the **CY8C624ABZI-D44 > System** tab.

9. Select the Resource **Power**, and in the **Power – Parameters** pane change the following parameters:
 - System Active Power Mode: LP -> ULP
 - Core Regulator: Normal Current LDO -> Buck

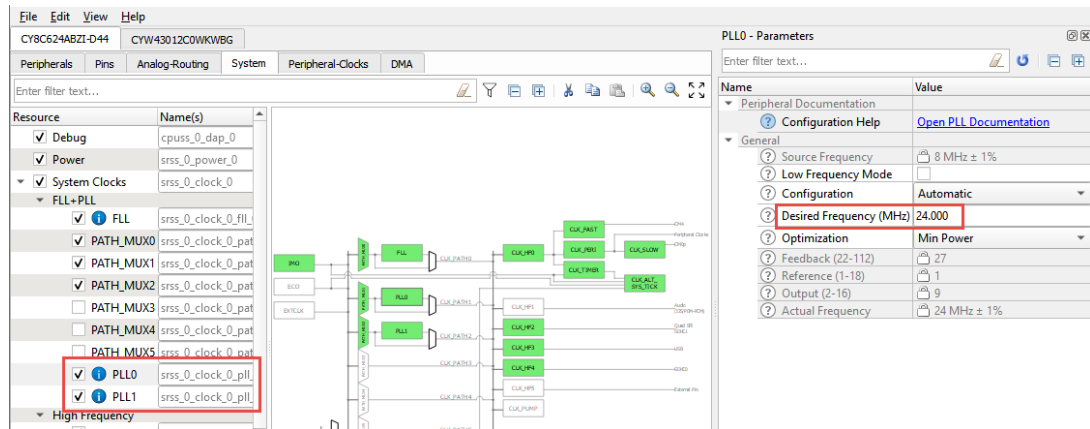

10. Select the Resource **System Clocks > FLL + PLL > FLL**

11. In the **FLL – Parameters** pane change the Desired Frequency (MHz) to 24:

12. In the **PLL0 – Parameters** and **PLL1 – Parameters** panes change the Desired Frequency (MHz) to 24:

13. Click **File > Save**.
14. Build and program the application.
15. Verify that the application works as expected by touching the slider and buttons.
16. Measure current consumption with the LED off and on at maximum brightness. What is the consumption you see?

LED off: _____ LED on: _____ (Lower Power Regulators and Slower Clocks)

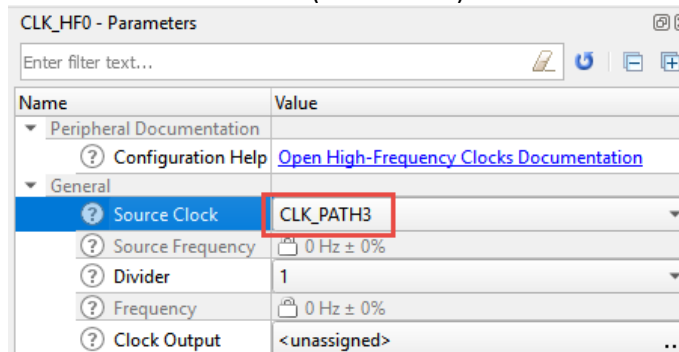

Disable Unused Chip Resources

Next let's disable the chip resources we don't use and further slow the high frequency clock CLK_HF0 by changing its source.

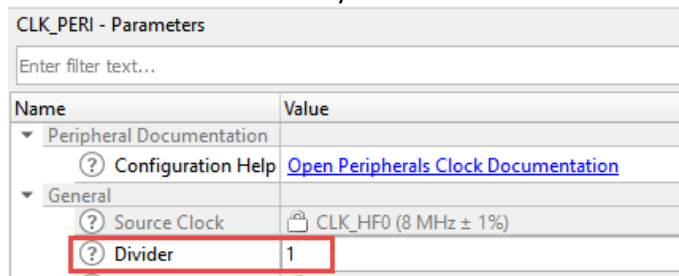

17. Open the Device Configurator by double-clicking on the custom design.modus file.
18. Navigate to **CY8C624ABZI-D44 > System** tab
19. Expand the Resource **System Clocks**, and do the following:

Change the source for CLK_HF0 to CLK_PATH3. This selects the IMO (8 MHz) as the clock source instead of the FLL (min 24MHz).

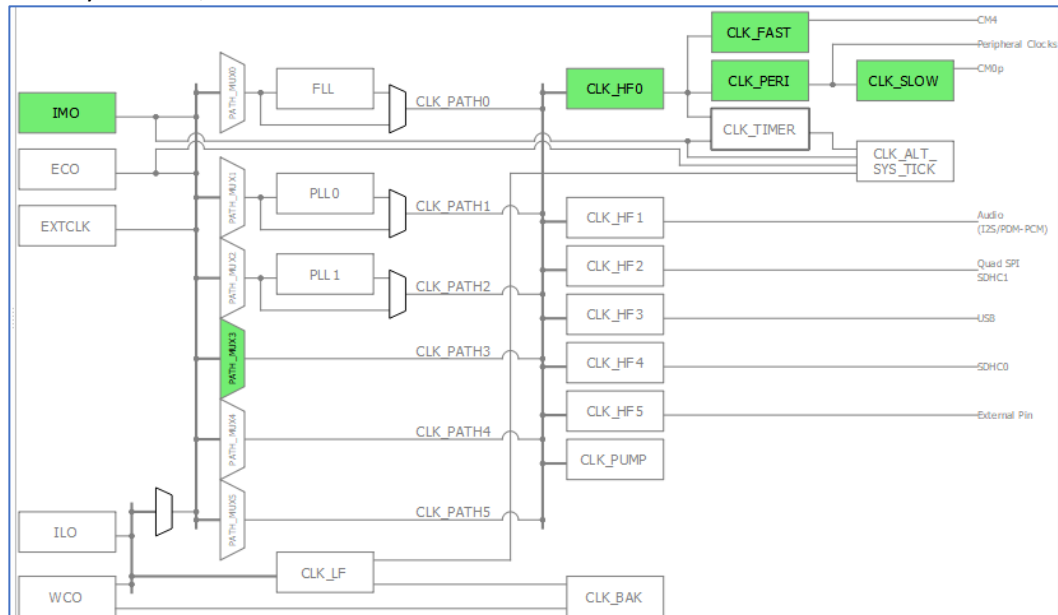

Change the divider for CLK_PERI to 1. This clock is used for CapSense so we don't want it slowed more than necessary.

Uncheck all listed clocks except these:

- FLL + PLL
 - a. PATH_MUX3 (Used to mux the IMO to CLK_HF0)
 - High Frequency
 - a. CLK_FAST (CM4 clock)
 - b. CLK_HF0 (Source for CLK_FAST)
 - c. CLK_PERI (Peripheral clock)
 - d. CLK_SLOW (CM0+ clock)
 - Input
 - a. IMO (Internal Main Oscillator - main clock source - 8 MHz)
- Miscellaneous (all unchecked)

When you finish, the clock tree should look like this:

20. Unselect (Disable) Resource **Debug**.
21. Navigate to the **Pins** tab and unselect the Debug pins - P6[4], P6[6] and P6[7] - and the WCO pins - P0[0] and P0[1]. The remaining pins are all used for CapSense.
22. Click **File > Save**.
23. In the Eclipse IDE menu, select **Project > Build Configurations > Set Active > Release**.
24. Build and program the application.
25. Verify that the application works as expected by touching the slider and buttons.
26. Measure current consumption with the LED off and on at maximum brightness. What is the consumption you see?

LED off: _____ LED on: _____ (Disable Unused Resources)

Enable Sleep

Finally let's optimize the application code to use sleep mode.

27. Open main.c file and add the highlighted line as follows:

```
/* Start first scan */
Cy_CapSense_ScanAllWidgets(&cy_capsense_context);

for(;;)
{
    cyhal_syspm_sleep();
    if(CY_CAPSENSE_NOT_BUSY == Cy_CapSense_IsBusy(&cy_capsense_context))
    {
        /* Process all widgets */
        Cy_CapSense_ProcessAllWidgets(&cy_capsense_context);
    }
}
```

The added line puts the CPU to sleep while a CapSense scan is running. When the scan finishes, it will issue an interrupt to wake the CPU so that it can process the results.

28. Click **File > Save**.
29. Build and program the application.
30. Verify that the application works as expected by touching the slider and buttons.
31. Measure current consumption with the LED off and on at maximum brightness. What is the consumption you see?

LED off: _____ LED on: _____ (Utilize Sleep Mode)

Note: The CapSense block does not operate in Deep Sleep. Since the application restarts a CapSense scan as soon as the previous scan completes, using Deep Sleep would not save any power because CapSense is always busy and therefore the application would never enter Deep Sleep.

To fix this you would need to add a low power timer to start scans periodically instead of running them continuously. You would also need to use the `Cy_SysPm_RegisterCallback` function to register a callback to the `Cy_CapSense_DeepSleepCallback` function. That function tells the system not to enter sleep unless the CapSense block is not currently performing a scan.

You will see how to do this in the FreeRTOS CapSense example. That example already does a scan every 10ms instead of continuously, so the timer part is already taken care of.

5d.6 Low Power in FreeRTOS

When using Low Power in FreeRTOS, the application must provide a function that knows how to optimize sleep for our hardware. The RTOS abstraction library provides a function called `vApplicationSleep` that understands how to optimize sleep for our hardware but FreeRTOS must be configured to use it during the idle state.

To set up the tickless idle mode to use the custom sleep handler, you must do the following:

1. Add the `abstraction-rtos` library to the application.
2. Edit the application's makefile:
 - a. Add `COMPONENTS+=FREERTOS` to the application's Makefile. This causes the FreeRTOS specific code from the abstraction-rtos library to be included in the build.

3. Edit the `FreeRTOSConfig.h` file:

- a. Remove:

```
#define configUSE_TICKLESS_IDLE 0
```

- b. Add:

```
#include "cycfg_system.h"

/* Sleep and Deep Sleep Handler Configuration */
#if (CY_CFG_PWR_SYS_IDLE_MODE == CY_CFG_PWR_MODE_SLEEP) ||
(CY_CFG_PWR_SYS_IDLE_MODE == CY_CFG_PWR_MODE_DEEPSLEEP)
extern void vApplicationSleep( uint32_t xExpectedIdleTime );
#define portSUPPRESS_TICKS_AND_SLEEP( xIdleTime ) vApplicationSleep( xIdleTime )
#define configUSE_TICKLESS_IDLE 2
#endif

/* Deep Sleep Latency Configuration */
#if CY_CFG_PWR_DEEPSLEEP_LATENCY > 0
#define configEXPECTED_IDLE_TIME_BEFORE_SLEEP CY_CFG_PWR_DEEPSLEEP_LATENCY
#endif
```

4. Select the desired Idle mode (CPU Sleep or System Deep Sleep) from the **System > Power > RTOS > System Idle Power Mode** setting in the Device Configurator.

The LP timer provided in the HAL is used to handle timing during sleep instead of any FreeRTOS timers. The timer is configured in the `vApplicationSleep` function, but it is necessary for the application device configuration to have `CLK_LF` enabled to allow the LP timer to operate.

If your application needs any specific actions associated with low power entry/exit, you can register a callback function that the PM system will call for you. You do this by calling either the HAL function `cyhal_syspm_register_callback` or the PDL function `Cy_SysPm_RegisterCallback`. Both take pointers to different (but similar) structures. Since the CapSense library uses all PDL functions, we will

use the latter in the exercise to be consistent. It takes a pointer to a structure of type `cy_stc_syspm_callback_t`:

```
typedef struct cy_stc_syspm_callback
{
    Cy_SysPmCallback callback;
    cy_en_syspm_callback_type_t type;
    uint32_t skipMode;

    cy_stc_syspm_callback_params_t *callbackParams;
    struct cy_stc_syspm_callback *prevItm;

    struct cy_stc_syspm_callback *nextItm;
    uint8_t order;
} cy_stc_syspm_callback_t;
```

callback: The first entry is the name of the callback function.

type: The second entry allows you to specify which type of low power mode the function should be called for. The supported values for `type` are:

```
CY_SYSPM_SLEEP
CY_SYSPM_DEEPSLEEP
CY_SYSPM_HIBERNATE
CY_SYSPM_LP
CY_SYSPM_ULP
```

skipMode: By default, the callback function will be called for 4 different events related to the `type` selected. The events are as follows. If you do NOT want the callback to be called for one or more of these events, add them to `skipMode`.

```
CY_SYSPM_CHECK_READY    /**< Callbacks with this mode are executed before
                           entering the low power mode. The purpose of this callback
                           function is to check if the device is ready to enter the
                           low power mode. */
CY_SYSPM_CHECK_FAIL     /**< Callbacks with this mode are executed after the
                           CY_SYSPM_CHECK_READY callbacks execution returns
                           CY_SYSPM_FAIL. The callback with the CY_SYSPM_CHECK_FAIL
                           mode should roll back the actions performed in the
                           previously executed callback with CY_SYSPM_CHECK_READY */
CY_SYSPM_BEFORE_TRANSITION /**< Callbacks with this mode are executed after the
                           CY_SYSPM_CHECK_READY callbacks execution returns
                           CY_SYSPM_SUCCESS. Performs the actions to be done before
                           entering the low power mode. */
CY_SYSPM_AFTER_TRANSITION /**< Performs the actions to be done after exiting the
                           low power mode. */
```

callbackParams: This entry allows you to pass parameters required by the callback function. It is a structure containing the base address of a HW instance and context. These may be NULL when a HW instance is not used or where a context is not needed.

prevItm and nextItm: The structure has pointers to a previous and next entry, so you can build a linked-list of callback structures if an application requires multiple callback functions.

See the *SysPm Callbacks* section in the SysPm PDL documentation for more information. You will also get a chance to try this in the exercise.

5d.6.1 Exercise 3: Improving Power Consumption for a FreeRTOS Application

In addition to the CapSense example that we looked at previously, there is a FreeRTOS version of the same example that uses FreeRTOS. Unlike the previous example, instead of running scans continuously, this one uses a FreeRTOS timer to start a new scan every 10 ms. Let's see how to improve power consumption on this application.

Most of the steps are the same as the other CapSense exercise except:

- The low frequency clock (CLK_LF) must be turned on as a wakeup source for the Low Power timer, which is used to wake FreeRTOS from CPU Sleep and System Deep Sleep.
- Instead of manually entering low power modes manually from the code, we will configure FreeRTOS to enter CPU Sleep or System Deep Sleep whenever it is idle.
- We will add a final step to use System Deep Sleep in this application to maximize power savings. This will save power since the application doesn't do CapSense scanning continuously.

As with the previous CapSense exercise, we will reduce the frequency of several clocks which affect the CapSense scan times. In this case, the design has enough margin to still operate properly. In a real application, you may need to re-tune CapSense parameters after changing clocks that affect it.

Create CapSense Design

1. Create the *CapSense Buttons and Slider FreeRTOS* Example for the CY8CKIT-062S2-43012 board using the Eclipse IDE. Name the application **ch05d_ex03_capsense_freertos**.
2. Build and Program the board. After programming, the application starts automatically.
3. Verify that the application works as expected by touching the slider, the LED brightness should correspond to the touch position. The buttons can be used to turn the LED on/off.
4. Measure current consumption with the LED off and on at maximum brightness. What is the consumption you see?

LED off: _____ LED on: _____ (Baseline)

Improve Power Consumption

Now do the following steps to improve power consumption of the application.

5. Rather than create a custom configuration from scratch, let's copy over the one from the previous exercise to use as a starting point.

- a. Copy the entire directory `ch05d_ex02_capsense/TARGET_CY8CKIT-062S2-43021` to the new application's top directory.

6. Edit the Makefile as follows and save when you are done:

- a. Add `CUSTOM_DESIGN_MODUS` to the `COMPONENTS` variable.

`COMPONENTS+=CUSTOM_DESIGN_MODUS`

- b. Add `BSP_DESIGN_MODUS` to the `DISABLE_COMPONENTS` variable.

`DISABLE_COMPONENTS+=BSP_DESIGN_MODUS`

7. In the Eclipse IDE menu, select **Project > Build Configurations > Set Active > Release**.

8. Build and program the application.

9. Verify that the application works as expected by touching the slider and buttons.

10. Measure current consumption with the LED off and on at maximum brightness. What is the consumption you see?

LED off: _____ LED on: _____ (Lower Power Regulators and Slower Clocks)

Enable CPU Sleep

Now let's allow FreeRTOS to use CPU Sleep during its Idle time.

- Open the library manager and add the abstraction-rtos library to the application.

- Add FREERTOS to the COMPONENTS variable in the application's Makefile. This will include the FreeRTOS specific code from the abstraction-rtos library into the build.

```
COMPONENTS+=CUSTOM_DESIGN_MODUS FREERTOS
```

- Open FreeRTOSConfig.h from the application's root directory and make the following changes:

Remove:

```
#define configUSE_TICKLESS_IDLE 0
```

Add:

```
#include "cycfg_system.h"

/* Sleep and Deep Sleep Handler Configuration */
#if (CY_CFG_PWR_SYS_IDLE_MODE == CY_CFG_PWR_MODE_SLEEP) ||
(CY_CFG_PWR_SYS_IDLE_MODE == CY_CFG_PWR_MODE_DEEPSLEEP)
extern void vApplicationSleep( uint32_t xExpectedIdleTime );
#define portSUPPRESS_TICKS_AND_SLEEP( xIdleTime ) vApplicationSleep(
xIdleTime )
#define configUSE_TICKLESS_IDLE 2
#endif

/* Deep Sleep Latency Configuration */
#if CY_CFG_PWR_DEEPSLEEP_LATENCY > 0
#define configEXPECTED_IDLE_TIME_BEFORE_SLEEP CY_CFG_PWR_DEEPSLEEP_LATENCY
#endif
```

- Open the Device Configurator by double-clicking on the custom design.modus file and select the **CY8C624ABZI-D44 > System** tab.

- Select Resource **Power** and in the **Power - Parameters** set the **RTOS > System Idle Power Mode** to **CPU Sleep**.

- In the Resource **System Clocks**, enable the ILO and CLK_LF. Set the source for CLK_LF as the ILO. Remember that this is required for the Iptimer that will wake the device from sleep. Click File > Save when you are done.

- Build and program the application. Verify that the application works as expected.

- Measure current consumption with the LED off and on at maximum brightness. What is the consumption you see?

LED off: _____ LED on: _____ (Utilize Sleep Mode)

Enable System Deep Sleep

Finally, we will allow FreeRTOS to use Deep Sleep instead of CPU Sleep during its idle time.

19. Open the Device Configurator by double-clicking on the custom design.modus file and select the **CY8C624ABZI-D44 > System** tab.
20. Select Resource **Power** and in the **Power - Parameters**, change the **RTOS > System Idle Power Mode** to **System Deep Sleep**. Save and close when you are done.

To allow Deep Sleep to work with CapSense, we need to give the power management system a way to know if CapSense is busy with a scan. To do this, we need to register a callback with the power management system. We'll do that now.

21. Open `capsense_task.c` and add two global structures.

These will be passed to the callback registration so that it knows about our CapSense block. In this case, we have only one structure, but the system allows for a linked-list of structures if you need processing for multiple parts of your design.

```
/* CapSense Deep Sleep handling setup */
/* Parameter structure for Sleep callback function */
cy_stc_syspm_callback_params_t CapSenseDeepSleepParams =
{
    CYBSP_CSD_HW,                // CapSense HW block base address
    &cy_capsense_context          // CapSense context
};

/* Callback Structure for Sleep callback function*/
cy_stc_syspm_callback_t CapSenseDeepSleep =
{
    &Cy_CapSense_DeepSleepCallback, // Provided by CapSense API
    CY_SYSPM_DEEPSLEEP,           // Callback for Deep Sleep Events
    0U, // Callback is executed for all DeepSleep events
    &CapSenseDeepSleepParams, // Callback parameters structure
    NULL, // No previous callback in the list
    NULL, // No next callback in the list
    0U // Priority order
};
```

22. In the same file, add the following line to the `task_capsense` function just before starting the scan timer.

```
/* Register CapSense Deep Sleep event callback */
Cy_SysPm_RegisterCallback(&CapSenseDeepSleep);
```

23. Build and program the application.
24. Verify that the application works as expected by touching the slider and buttons.
25. Measure current consumption with the LED off and on at maximum brightness. What is the consumption you see?

LED off: _____ LED on: _____ (Utilize Deep Sleep Mode)

5d.7 Low Power Assistant for Wi-Fi Connected Devices

5d.7.1 Introduction

In this section we will learn how the Low Power Assistant helps you to minimize the MCU power consumption in a system connected to Wi-Fi.

As you learned previously, the PSoC 6 communicates with the Wi-Fi device using an SDIO interface. In addition to the SDIO interface, there is a pin dedicated for use in low power. This pin allows the Wi-Fi device to wake the PSoC 6 host. In this way, the PSoC 6 can go into a low power mode whenever its application allows, and the Wi-Fi device will wake it up only when it is needed to handle specific network activity.

Refer to the [LPA Library Guide Part 2](#) for additional information.

- LPO_IN (32 kHz): 32 kHz sleep clock used for low-power WLAN operation
- SDIO: Clock, Data
- WL_HOST_WAKE: Interrupt line to wake the Host to service Wi-Fi request

Once the wake pin is configured and the LPA library is available, you can offload various Wi-Fi operations such as responding to certain packet types so that they can either be handled by the Wi-Fi device locally.

5d.7.2 Exercise 4: Basic Low-Power for Wi-Fi Applications

Rather than start from scratch, we'll start with the WLAN Low Power code example to see how basic low power host wake is configured. In later exercises, we'll add various offloads so that the Wi-Fi device can handle more operations without the host MCU being involved.

Since this is an AnyCloud FreeRTOS application, all the setup required for low power in FreeRTOS as described in section 0 is already done.

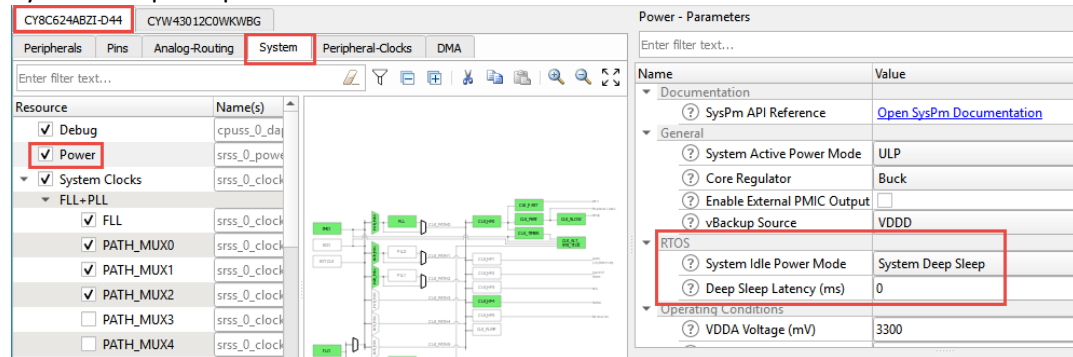

1. Create the *AnyCloud_WLAN_Low_Power* example for the CY8CKIT-062S2-43012 board using the Eclipse IDE. Name the application **ch05d_ex04_wlan_low_power**.

Once the application has been created, notice that it has a folder called COMPONENT_CUSTOM_DESIGN_MODUS. Inside that folder is a folder for each TARGET supported by the CE. The Makefile has already been set up to use this custom configuration.

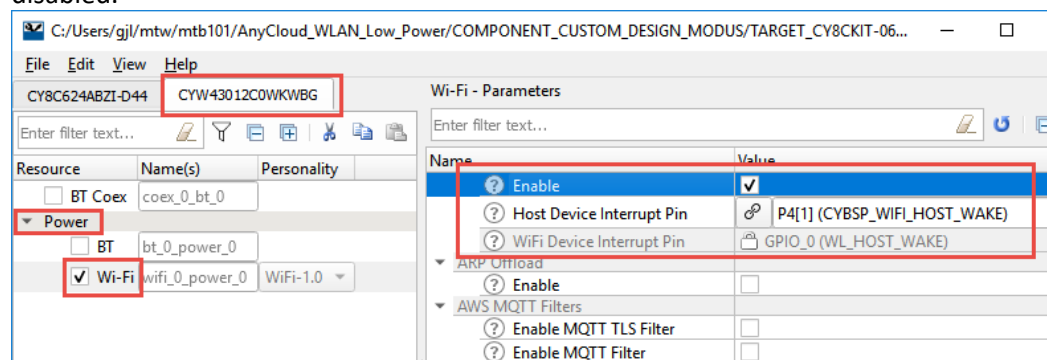

2. Open the custom design.modus file for your kit.

Notice that the Power settings for the PSoC 6 are configured such that the RTOS will use System Deep Sleep when it is idle.

3. Next, switch to the **CYW43012C0WKWBG** tab. This has settings for the WLAN device.
4. Click on **Power > Wi-Fi** to see the settings.

Notice that the Host Wake Configuration is enabled, and the Host Device Interrupt Pin is set to the correct pin for your kit. Also notice that all other Wi-Fi power controls are disabled.

With these settings, the WLAN device will not offload any tasks or filter any packets - it will wake the host CPU for any Wi-Fi activity. However, the PSoC 6 does configure the WLAN device for low power operation and suspends the network after periods of inactivity.

5. Open the file `lowpower_task.c` and look at the `lowpower_task` function.

Note that `lowpower_task` calls `wlan_powersave_handler` to configure the WLAN device for power save without throughput, power save with throughput, or power save disabled. It calls the appropriate `whd_wifi_*_powersave` functions to accomplish this. These functions are provided by the WHD library.

Also note that the `lowpower_task` will suspend the network when it has been inactive for a specified period of time by calling `wait_net_suspend`. This function is part of the LPA library.

6. Open the file `lowpower_task.h`. Update the **WIFI_SSID** and **WIFI_PASSWORD** to match the Wi-Fi network being used for the class.

```
#define WIFI_SSID "SSID"
#define WIFI_PASSWORD "PASSWORD"
```

7. Build and Program the board.

8. Open a UART terminal to verify that it successfully connects to Wi-Fi.

You will see that the Wi-Fi device will wake the host MCU to service many different broadcast and multicast packets issued by the AP such as ARP (Address Resolution Protocol) requests. The frequency and number of events will depend on how heavy network traffic is.

9. Open a command terminal and ping the kit to verify that it responds. Check the UART terminal to see that the host wakes up to service the ping event.

In the next exercises we will configure different offloads to further improve the time for which the host can remain in Deep Sleep.

5d.7.3 Exercise 5: Configure Packet Filter Offload

Packet filters allow the host processor to limit which types of packets get passed up to the host from the WLAN subsystem. This is useful to keep out unwanted / unneeded packets from the network that might otherwise wake the host out of a power-saving System Deep Sleep mode or prevent it from entering System Deep Sleep mode.

Packet filters are useful when:

- Trying to keep the host processor in System Deep Sleep for as long as possible.
- Trying to get the host processor into System Deep Sleep as soon as possible.

Whenever a WLAN packet is destined for the host, the WLAN processor must wake the host (if it is asleep) so it can retrieve the packet for processing. Often the host network stack processes the packet only to discover that the packet should be thrown away, because it is not needed. For example, it is destined for a port or service that is not being used. Packet filters allow these types of packets to be filtered and discarded by the WLAN processor, so the host is not woken.

Refer to the [Packet Filters Quick Start Guide](#) for additional information.

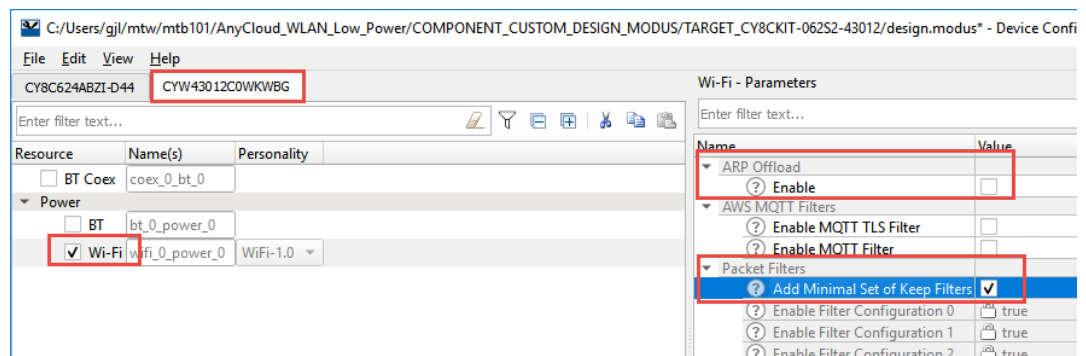

You can either edit the previous exercise, or if you want separate copies you can create a new application from the previous exercise (use the **Import** button in the Project Creator to select the previous application). If you choose to do that, call the new application **ch05d_ex05_packet_filter**. Once it is created, you may need to remove the launch configurations and re-create them.

1. Open the Device Configurator. Verify in the banner that you have the custom file for your application opened.
2. Switch to the connectivity device tab.

Enable **Add minimal set of keep filters**. Keep **ARP Offload** disabled for now.

These filters allow ARP, DNS, DHCP and 802.11x security packets to wake up the Host. These are needed to connect to a Wi-Fi Access point. Any other Wi-Fi packets will be dropped by the WLAN chip and not forwarded to the Host MCU (PSoc 6).

3. Save the configuration to generate the necessary code.

4. Open a UART terminal to see messages from the board.
5. Build the project and program. Observe the IP address assigned to your kit.
6. Open a command terminal and send a "ping" command to the board.

Observe the UART terminal or observe the power consumption to see that it does not wake up the PSoC 6 device since there is no "keep" packet filter for ICMP pings. Also observe that there is no response for the pings.

7. Send an "arping" command and observe that:
 - You get the responses.
 - Observe the UART terminal or observe the power consumption to see that the PSoC 6 MCU wakes up to service the ARP ping.

Note: If you are using Linux or MacOS, arping is built-in. On Windows, you will need to download a tool to send arping requests. One such tool can be found here:

<https://elifulkerson.com/projects/arp-ping.php>

To use that tool, download it onto your computer. Open a command terminal and go to the directory containing the downloaded file. Run the command:

```
.\arp-ping.exe <ip address>
```

In some cases, the arp-ping may respond with data from a cached ARP table on the PC instead of sending the request to the network. If that is the case, you can delete the table from the PC before each ARP ping by using the -d option, but this requires that you run the command terminal as administrator:

```
.\arp-ping.exe -d <ip address>
```

You can see what is in the cache by running:

```
arp -a
```

5d.7.4 ARP (Address Resolution Protocol) Offload

Recall that Wi-Fi devices will send broadcast ARP requests to all devices. When a device hears an ARP request for its IP address, it must respond with its MAC address - this is how devices figure out how to send packets through the network to the correct place. Devices often monitor and cache ARP responses for other devices that they hear on the network so that they can build up an ARP table of IP to MAC address that exist on the network. That way, they don't need to send ARP requests as often.

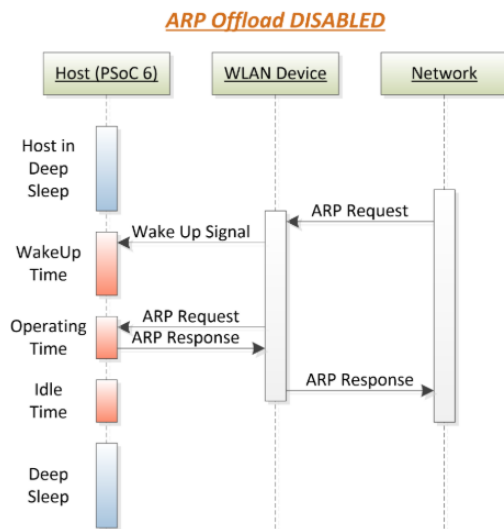

ARP traffic is normally forwarded from the WLAN device to the host MCU. If the Host is sleeping, the Device wakes it up. Having the Device handle some of the ARP traffic will reduce the frequency that the Host sleeps/wakes up, reducing Host power consumption by staying in CPU Sleep and System Deep Sleep states longer. By enabling ARP offload, the WLAN device will not wake the host for all ARP requests. Rather, it will send the response itself whenever an ARP request is addressed to it.

Likewise, when the host wants to send an ARP request, the WLAN device can respond directly without sending the request to the network if the WLAN device has the requested address cached.

The ARP offload features can be found in the LPA library documentation here: [ARP Offload features](#). The main features are summarized below.

Disabled

With ARP offload disabled, all ARP requests from the network will wake the host:

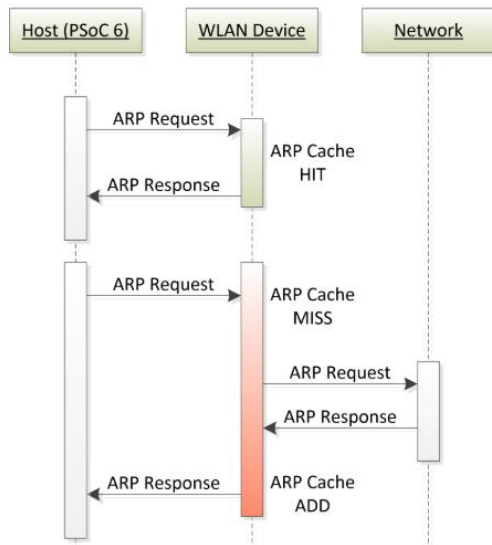

In addition, all ARP requests from the host will be sent out to the network by the WLAN device (this case is not shown).

Host Auto Reply

Host Auto Reply is a power-saving and network traffic reduction feature. Using the ARP Offload Host Auto Reply feature, the WLAN device will answer ARP requests from the host MCU without broadcasting the request to the Network if it has the requested information in its cache:

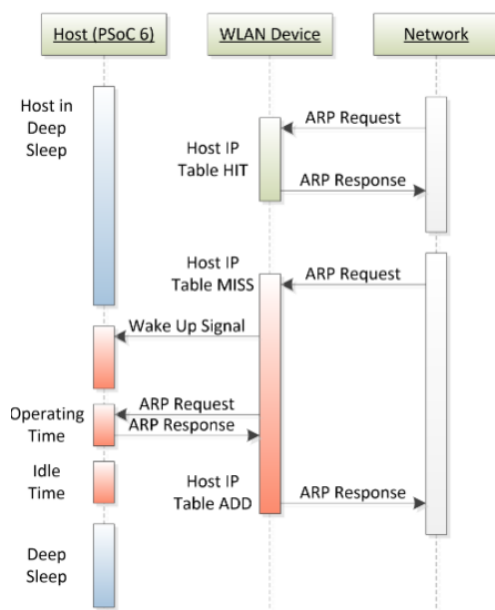

ARP Offload ENABLED: Agent, Host Auto Reply

Peer Auto Reply

Peer Auto Reply targets requests in the other direction. That is, the WLAN device will respond to ARP requests from Peers (i.e. from the network) without waking up the Host Processor:

ARP Offload ENABLED: Peer Auto Reply

Host IP Snoop

When enabled, the Snoop facility watches for ARP responses from the host to the network, and caches them in the WLAN Device Host IP Table. The size of this table is 8 entries, which allows for the Device to support multiple IP addresses.

ARP Offload Cache Entry Expiry

This is an "age out" value that you can set in the ARP Offload configuration to determine the length of time the ARP cache entry is valid. This ensures that the WLAN ARP cache is updated appropriately. Now let's add ARP Offload to our previous exercise.

5d.7.5 Exercise 6: ARP Offload

You can either edit the previous exercise, or if you want separate copies you can create a new application from the previous exercise (run the Project Creator, select your kit, and then use the Import button on the application selection screen to select the previous application). If you choose to do that, call the new application **ch05d_ex06_ARP_offload**.

1. Open the Device Configurator. Verify in the banner that the correct file is opened.
2. Switch to the connectivity device tab.

- Enable **ARP offload**.
- Set **ARP offload Feature(s)** to "Peer Auto Reply".
- Enable **Snoop Host IP From Traffic When ARP Offload Enabled**.
- Set **ARP Offload Cache Entries Expire after (s)** to "1200".
- Keep Packet Filters as configured.
- Save your changes.

3. Build the project and program.
4. Send a "ping" command to the board and observe no change in behavior.

In the UART terminal, you will see that it does not wake up the PSoC 6 device since there is no "keep" packet filter for ICMP pings. Observe the power consumption to see that the PSoC 6 MCU remains in Deep Sleep mode.

5. Send an "arping" command.
 - Observe that you still get the responses.
 - Observe the UART terminal and power consumption to see that the PSoC 6 MCU no longer wakes up.

The PSoC 6 (Host) is offloaded from ARP packet handling and can remain in sleep.

5d.7.6 Exercise 7: Allow ICMP (Ping) Packets Through the Filter

This explains how to modify Packet filters so that ICMP Ping packets are not filtered by the WLAN and are sent to the host.

You can either edit the previous exercise, or if you want separate copies you can create a new application from the previous exercise (use the Import button in the Project Creator to select the previous application). If you choose to do that, call the new application **ch05d_ex07_allow_ping**.

1. Open the Device Configurator. Verify in the banner that you have the correct file opened.
2. Switch to the connectivity device tab and select Resource **Power > Wi-Fi**

Check the box for **Enable Filter Configuration 4**.

Note: Filter configurations 0-3 are locked because they are used for the minimal set of keep filters that you previously added.

| Packet Filters | |
|-----------------------------------|-------------------------------------|
| ⓘ Add Minimal Set of Keep Filters | <input checked="" type="checkbox"/> |
| ⓘ Enable Filter Configuration 0 | <input type="checkbox"/> true |
| ⓘ Enable Filter Configuration 1 | <input type="checkbox"/> true |
| ⓘ Enable Filter Configuration 2 | <input type="checkbox"/> true |
| ⓘ Enable Filter Configuration 3 | <input type="checkbox"/> true |
| ⓘ Enable Filter Configuration 4 | <input checked="" type="checkbox"/> |

3. Scroll down and set the configuration for filter 4 as follows.

Refer to the LPA documentation for details:

[Packet Filters Quick Start Guide](#)
[Filter Types](#)

Filter Type set to "IP Type" (IP Protocol Filter)

IP Protocol set to "1" (1 refers to ICMP packet : [List of IP protocol numbers](#))

| Packet Filter Configuration 4 | |
|-------------------------------|---------------------------------|
| ⓘ Filter ID | <input type="text" value="4"/> |
| ⓘ Filter Type | IP Type |
| ⓘ Action | Keep |
| ⓘ When Active | <input type="checkbox"/> Always |
| ⓘ IP Protocol | 1 |

4. Save your changes, build the project and program.
5. Send a "ping" command to the board and observe the UART terminal.

It now wakes the Host up because you have just added a "keep" packet filter for ICMP pings. You can see the response in the terminal and can observe increased power consumption upon receiving the ping packet.

6. Send an "arping" command.

This behavior did not change; you get the responses to ARP in terminal while the PSoC 6 MCU remains in sleep.

5d.8 Low Power Assistant for BT Connected Devices

5d.8.1 Introduction

In this section we will learn how the Low Power Assistant helps you to minimize the MCU power consumption in a system using Bluetooth.

As you learned previously, the PSoC 6 communicates with the BT portion of the connectivity device using a UART interface. In addition to the UART interface, there are two pins dedicated for use in low power. These pins allow the BLE device to wake the PSoC 6 host and vice versa. In this way, either device can go into a low power mode whenever its application allows, and the other device can wake it up when it is needed to handle specific activity.

Refer to the [LPA Library Guide Part 3](#) for additional information.

- UART: (CTS / TXD / RXD / RTS)
- BT_HOST_WAKE (host wake): MCU input pin which can wake the MCU with interrupt.
- BT_DEV_WAKE (device wake): an output MCU host pin which is connected as input BT device pin which interrupts the BT device when set in active state.

5d.8.2 BT Low Power Configuration Structure

The BT configuration file (typically called `app_bt_cfg.c`) has a structure of type `cybt_platform_config_t`. That structure looks like this:

```
typedef struct
{
    cybt_hci_transport_config_t    hci_config;
    cybt_controller_config_t      controller_config;
    uint32_t                      task_mem_pool_size;
} cybt_platform_config_t;
```

The `controller_config` structure inside that looks like this:

```
typedef struct
{
    cyhal_gpio_t                  bt_power_pin;
    cybt_controller_sleep_config_t sleep_mode;
} cybt_controller_config_t;
```

Finally, the sleep_mode structure inside there has the sleep mode configuration settings:

```
typedef struct
{
    uint8_t          sleep_mode_enabled;
    cyhal_gpio_t     device_wakeup_pin;
    cyhal_gpio_t     host_wakeup_pin;
    uint8_t          device_wake_polarity;
    uint8_t          host_wake_polarity;
} cybt_controller_sleep_config_t;
```

These settings include one value to enable or disable the sleep mode, settings for the Host Wake and Dev Wake pins, and settings to configure the polarity for the Host Wake and Dev wake pins.

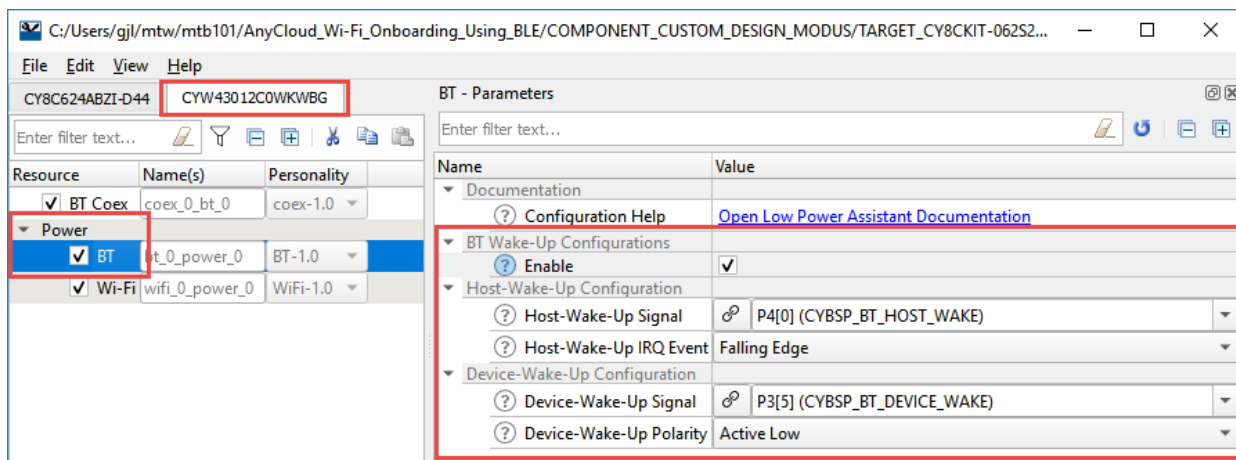

Rather than set these values manually in the BT configuration file, we want the settings in the **Power > BT** section of the Device Configurator for the connectivity device to control them, so in the app_bt_cfg.c you would typically want something like this for the controller configuration entry:

```
.sleep_mode =
{
    /* For ModusToolBox BT LPA configuration */
    #if defined(CYCFG_BT_LP_ENABLED)
    .sleep_mode_enabled = CYCFG_BT_LP_ENABLED,
    .device_wakeup_pin = CYCFG_BT_DEV_WAKE_GPIO,
    .host_wakeup_pin = CYCFG_BT_HOST_WAKE_GPIO,
    .device_wake_polarity = CYCFG_BT_DEV_WAKE_POLARITY,
    .host_wake_polarity = CYCFG_BT_HOST_WAKE_IRQ_EVENT
    #else
    .sleep_mode_enabled = false,
    #endif
}
```

You also need this include at the top of the file to get access to the LPA defines.

```
#include "cycfg.h"
```

From the device configurator, you then have configuration choices as shown here:

On the PSoC 6 side of things, the pins are initialized by the bluetooth-freertos library so you don't need to worry about them.

5d.8.3 Exercise 8: Wi-Fi Onboarding Using BLE

Again, rather than starting from scratch, we will use the AnyCloud Wi-Fi Onboarding Using BLE as a starting point. The example runs a BLE GATT server with a custom service. The service allows you to use a BLE connection to enter your Wi-Fi AP SSID and password. Once that's done, it will connect to the AP using the credentials you supplied. The credentials are stored in non-volatile memory so that on a reset or power cycle, the kit will automatically reconnect to the same AP.

Since this is a low-power AnyCloud FreeRTOS application, all the setup required for low power in FreeRTOS as described in section [5d.6 Low Power in FreeRTOS](#) is already done.

For this exercise, we will be measuring the current consumption of the connectivity device while BLE is connected.

1. First, disconnect your kit from the computer and then move the ammeter from J15 to J8.
Don't forget to re-install the shunt for J15. Once that's done, make sure the ammeter is turned on and plug the kit back into your computer.

2. Create the *AnyCloud_Wi-Fi_Onboarding_Using_BLE* example for the CY8CKIT-062S2-43012 board.

3. Name the application **ch05d_ex07_wifi_ble_onboarding**.

This application already has a folder called COMPONENT_CUSTOM_DESIGN_MODUS. Inside that folder is a folder for each TARGET supported by the CE. The Makefile has already been set up to use this custom configuration.

4. Open the custom design.modus file for your kit

Notice that the Power settings for the PSoC 6 are configured such that the RTOS will use System Deep Sleep when it is idle.

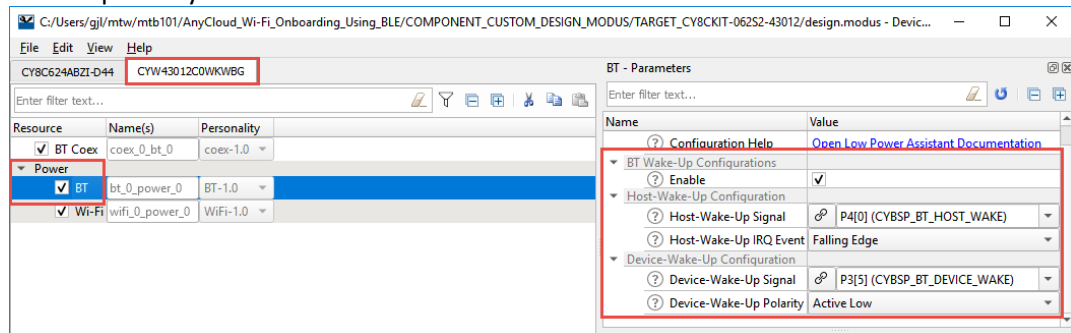

The screenshot shows the PSoC Creator interface with the 'System' tab selected. The 'Power - Parameters' window is open on the right, showing the 'System Idle Power Mode' set to 'System Deep Sleep'. The 'Deep Sleep Latency (ms)' is set to 0. The 'VDDA Voltage (mV)' is set to 3300.

5. Next, switch to the **CYW43012C0WKWBG** tab. This has settings for the connectivity device.

6. Select **Power > BT** to see the BT settings.

Notice that the **BT Wake-Up Configurations** is enabled, and the pins are set to the correct pin for your kit.

With these settings, the PSoC 6 and BT device can each wake the other when they need attention.

Note: The pin settings such as drive mode and interrupt callback for the host wake-up and device wake-up signals is done in the file `cybt_platform_freertos.c` in the bluetooth-freertos library. Therefore, you will not see those pin settings in the device configurator for the PSoC 6 device.

7. Open the Bluetooth Configurator and give your device a unique name such as `<Inits>_prov`. Make sure you press Enter so the length is updated.
8. At the top of `main.c`, add an include for the HAL:

```
#include "cyhal.h"
```

9. At the top of the `application_init` function in `main.c`, add the following to generate a unique Bluetooth Device Address.

```
/* Generate a random local Bluetooth Device Address and print it out */
wiced_bt_device_address_t bda = {0};
cyhal_trng_t trng_obj;
cyhal_trng_init(&trng_obj);

wiced_bt_set_local_bdaddr( bda, BLE_ADDR_RANDOM);
```

10. Review `main.c` and `wifi_task.c` to understand how the application works.
11. Open a UART terminal window and program the kit.
12. Use your phone to connect to your kit over BLE.

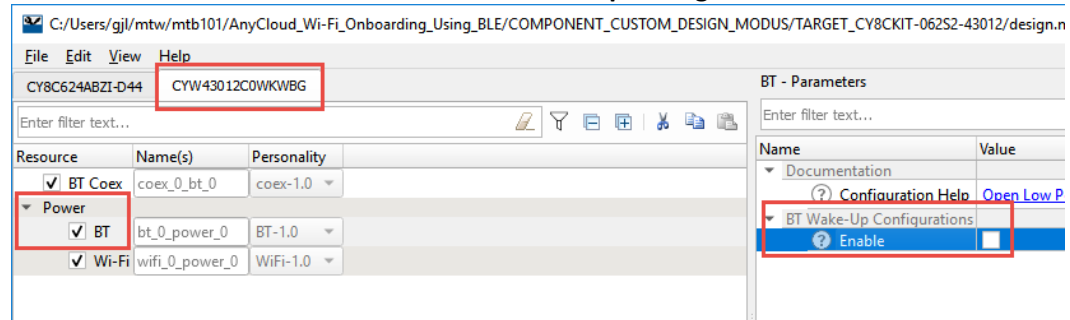

- a. Open the GATT database viewer and select the custom Service.
- b. Measure the current of the connectivity device.
- c. You may need to record the largest and smallest values you see since it will change.

_____ Connectivity Device Current (Low Power Enabled)

13. Disconnect from the kit from your phone.

14. Open the Device Configurator and make the following change to the connectivity device settings:

Uncheck the box next to **Power > BT > BT Wake-Up Configurations Enable**

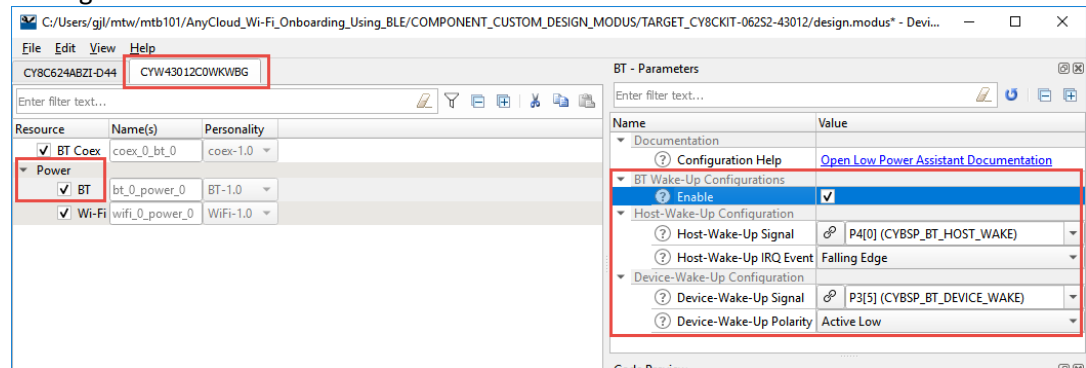

15. Reprogram the kit and reconnect to it from your phone over BLE.

16. Repeat the current measurement on the connectivity device.

_____ Connectivity Device Current (Low Power Disabled)

17. Open the Device Configurator and change the setting back to the original values.

Check the box next to **Power > BT > BT Wake-Up Configurations Enable** The other settings should have been retained.

18. Reprogram the kit and follow the instructions in the Operation section of the application's README.md to use BLE to connect the kit to the Wi-Fi AP.

19. Look at the UART terminal to verify that the kit has successfully connected to Wi-Fi.
